Solving security-constrained ACOPF problems

Daniel Bienstock, Columbia University and Gurobi Richard Waltz, Artelys

## A formal textbook statement of standard ACOPF

Minimize cost of generation: $\sum_{\boldsymbol{g} \in \mathcal{G}} \boldsymbol{F}_{\boldsymbol{g}}\left(\boldsymbol{P}^{\boldsymbol{g}}\right)$

- Here, $\mathcal{G}$ is the set of generators
- $\boldsymbol{P}^{\boldsymbol{g}}$ is the (active) power generated at $\boldsymbol{g}$
- $\boldsymbol{F}_{\boldsymbol{g}}$ is generation cost at $\boldsymbol{g}$-convex, piecewise-linear or quadratic Example: $\boldsymbol{F}_{g}(\boldsymbol{P})=3 \boldsymbol{P}^{2}+2 \boldsymbol{P}$
Constraints:
- PF (power flow) constraints: choose voltages so that network delivers power from generators to the loads
- Voltage magnitudes are constrained
- Power flow on any line $\boldsymbol{k m}$ cannot be too large: $\left|\boldsymbol{S}_{\boldsymbol{k} \boldsymbol{m}}\right|$ is within limits
- The output of any generator is limited

Minimize $\sum_{g \in \mathcal{S}} F_{g}\left(\boldsymbol{P}^{\boldsymbol{g}}\right)$
with constraints:

$$
\begin{aligned}
& \boldsymbol{S}_{k m}= \\
& \left(G_{k k}-j B_{k k}\right)\left|\boldsymbol{V}_{k}\right|^{2}+\left(G_{k m}-j B_{k m}\right)\left|\boldsymbol{V}_{k}\right|\left|\boldsymbol{V}_{m}\right|\left(\cos \boldsymbol{\theta}_{k m}+j \sin \theta_{k m}\right) \\
& \sum_{k m \in \delta(k)} \boldsymbol{S}_{\boldsymbol{k m}}=\left(\sum_{\boldsymbol{g} \in \boldsymbol{G}(k)} \boldsymbol{P}^{\boldsymbol{g}}-P_{k}^{d}\right)+j\left(\sum_{\boldsymbol{g} \in \boldsymbol{G}(k)} \boldsymbol{Q}^{\boldsymbol{g}}-Q_{k}^{d}\right)
\end{aligned}
$$

Power flow limit on line $k m$ :
$\left|\boldsymbol{S}_{\boldsymbol{k} \boldsymbol{m}}\right|^{2}=\mathcal{R e}\left(\boldsymbol{S}_{\boldsymbol{k} \boldsymbol{m}}\right)^{2}+\operatorname{Im}\left(\boldsymbol{S}_{\boldsymbol{k} \boldsymbol{m}}\right)^{2} \leq U_{k m}$
Voltage limit on node $k$ :
$V_{k}^{\min } \leq\left|V_{k}\right| \leq V_{k}^{\max }$

Generator output limit on node $k$ :
$P_{k}^{\min } \leq \boldsymbol{P}_{k}^{\boldsymbol{g}} \leq P_{k}^{\max }$
Phase angle limit on line km : (sometimes)
$\left|\theta_{k}-\theta_{m}\right| \leq \theta_{k, m}^{\max }$

## GO competition: basic features

- Maximize surplus rather than minimize cost
- Piecewise-linear function measuring benefit of consumption (for each load)
- Imbalance, line overload, transformer overload penalty functions (more below)
- Switched shunt step selection
- Tap ratio, phase shift, impedance correction for transformers
- Topology optimization
- Generator commitment, start-up and shut-down decisions
- Security-constrained: total objective is sum of base case plus average contingency case
- More

GO competition: configurable transformers and shunts

- Example: tap ratio and angle in a transformer can be adjusted

- Impedance correction factors modeled using a piecewise-linear curve

- Function can be quite nonlinear with local optima
- Switched shunts, in blocks (at buses)
- Altogether, a large number of integer variables

## GO competition: contingencies

- We are given a (often, large) list of $\boldsymbol{K}$ contingencies
- "Line out" contingency - one power line fails
- "Gen out" contingency - one generator
- For each contingency $\boldsymbol{k}$, a feasible solution $\boldsymbol{V}^{\boldsymbol{k}}, \boldsymbol{G}^{\boldsymbol{k}}, \boldsymbol{L}^{\boldsymbol{k}}, \boldsymbol{Z}^{k}$ must be computed
- The system should be able to migrate from base solution to the contingency solution
- Again, with restrictions: e.g. the difference between base $G^{b}$ and contingency $G^{k}$ is constrained
- Total cost $=$
cost of base solution $+\frac{1}{K} \sum$ cost of solution to contingency $\mathbf{k}$

## GO competition: handling equation mismatches

- ACOPF model abounds with nonlinear equations. Example:
$\sum_{k m \in \delta(k)} \boldsymbol{V}_{k} \boldsymbol{I}_{k m}^{*}=\left(\sum_{\boldsymbol{g} \in \boldsymbol{G}(k)} \boldsymbol{P}^{\boldsymbol{g}}-P_{k}^{d}\right)+j\left(\sum_{\boldsymbol{g} \in G(k)} \boldsymbol{Q}^{\boldsymbol{g}}-Q_{k}^{d}\right)$
- Challenge! When presented with a nonlinear equation,

$$
F(x)=0,
$$

a numerical solver will instead return $\hat{x}$ with $\boldsymbol{F}(\hat{\boldsymbol{x}})=\boldsymbol{\epsilon}$ with $|\epsilon|$ small (usually)

- And then, what?

A little infeasibility can buy you a lot of optimality

- GO competition Add to the objective a term of the form $L(|\epsilon|)$ where $L$ is rapidly increasing convex (infeasibility penalization)
- This difficulty is of a fundamental nature!

## GO competition: Prior Solution

- $\boldsymbol{V}^{\text {prev }}, \boldsymbol{G}^{\text {prev }}, \boldsymbol{L}^{\text {prev }}, \boldsymbol{Z}^{\text {prev }}=$ existing solution (voltage, generation, controllable loads, configuration)
- To compute: $\boldsymbol{V}^{b}, G^{b}, \boldsymbol{L}^{b}, \boldsymbol{Z}^{b}=$ new (base) solution
- Why a new solution? Because e.g. some of the fixed loads may change. And the network may be slightly different.
- Restrictions: e.g., the difference between $G^{\text {prev }}$ and $G^{b}$ is constrained

$$
\left|\boldsymbol{P}^{g, \text { prev }}-\boldsymbol{P}^{g, b}\right| \leq \text { upper bound dependent on } g
$$

for each generator $g$.
$\rightarrow$ The prior solution is more help than hindrance!

## GO competition: data sets

- Combination of industry and realistic synthetic data sets
- Both large and with many contingencies
- Industry example C2T2N34363:
$\mathbf{3 4 , 0 0 0}$ buses, 41,000 lines, 900 generators, $\mathbf{3 0 0 0}$ contingencies thousands of integer variables
- A single ACOPF run on such networks is nontrivial: Example C2FEN19402:
- 19,402 buses, 968 generators, 13,000 lines
- 267904 variables, 200890 constraints, 6692 contingencies
- KNITRO solves Base case in 51.05 seconds on 11 cores.
- Available time is limited: 5 minutes to one hour

## The king of the hill - log barrier methods

Example: $\min \left\{g\left(v_{1}, v_{2}\right): 1 / 2 \leq v_{1}\right.$ and $\left.v_{2} \leq 1\right\}$ where $g$ is convex

## becomes:

$\min g\left(v_{1}, v_{2}\right)-\alpha \log \left(v_{1}-1 / 2\right)-\alpha \log \left(1-v_{2}\right)$
subject to: $\quad v_{1}, v_{2}$ unconstrained

$$
\alpha>0 \text { a "barrier" parameter (small!) }
$$

## The king of the hill - log barrier methods

Minimize $f(x)$
s.t. $c(x)=0$
$x \geq 0$

Instead, solve barrier problems:
Minimize $f(x)-\mu \sum_{j=1}^{n} \ln \left(x_{j}\right)$
s.t. $c(x)=0$

And let $\boldsymbol{\mu} \boldsymbol{\boldsymbol { 0 }}$. Primal-dual equations:

$$
\begin{aligned}
\nabla f(x)-\mu \nabla c(x)-z & =0 \\
c(x) & =0 \\
z_{j} x_{j} & =\mu \quad \text { all } j
\end{aligned}
$$

Solve this system, for each fixed $\mu$, using Newton's method

## The king of the hill - log barrier methods

Today, two implementations dominate:

- KNITRO (Waltz, Nocedal, 2003): A "merit function" method.
- IPOPT (Wachter and Biegler, 2004): A "filter" method.

KNITRO and IPOPT followed a long line of work due to many authors!

1. Log barrier methods can (very closely) optimize very large ACOPF problems in minutes
2. Nothing else comes close. Relaxation methods only prove bounds - don't provide solutions
3. Relaxation methods: spatial branch-and-cut, semidefinite programming, others.

## The king of the hill - log barrier methods

Today, two implementations dominate:

- KNITRO (Waltz, Nocedal, 2003): A "merit function" method.
- IPOPT (Wachter and Biegler, 2004): A "filter" method.

KNITRO and IPOPT followed a long line of work due to many authors!

1. Log barrier methods can (very closely) optimize very large ACOPF problems in minutes
2. Nothing else comes close. Relaxation methods only prove bounds - don't provide solutions
3. New kid on the block: Gurobi. Integrated log-barrier, integer programming and relaxations!

## We were \# 2 overall

Basic approach:

1. Dimensionality reduction

- Fact: real-world power systems are very robust
- Transition from previous solution, to base solution should require minor adjustments
- Transition from base solution, to contingency solutions should require minor adjustments

2. Progressive rounding

Common-sense iterative rounding of integer variables all integer variables modeled as sum of binaries
3. Numerical stability

Some numerical parameters in GO setup are too large.
Slack penalty function in particular. Replaced with simple linear penalty plus bounds.

## Dimensionality reduction

Example: transition from previous solution, to base solution

- Most changes in data from previous network, to new one, involve changes in demands
- Most demand changes are very small
- What we did:

1. Select a subset $\boldsymbol{S}$ of buses with large enough demand changes
2. Restrict changes in prior solution to buses that are electrically close enough to $\boldsymbol{S}$
3. Apply our rounding heuristic to the correspondingly restricted ACOPF problem

## C2T3N06100 scenario 115

## 6476 buses, 3371 loads, 406 generators, 5337 lines, 3086 transformers, 2467 contingencies

- About 100,000 variables and constraints
- Picture shows buses where prior solution has infeasibility greater than 1e-3: about 200

```
obj=712281.64
total_bus_cost 1.85847217e-02
total_load_benefit 1.26257799e+06
total_gen_cost 5.50296330e+05
total_line_cost 0.00000000e+00
total_xfmr_cost 0.00000000e+00
(Knitro feaserror 2.481e-09)
169.05 sec 450 iterations
```

## C2T3N06100 scenario 115

6476 buses, 3371 loads, 406 generators, 5337 lines, 3086 transformers, 2467 contingencies
Contingency 3 (line down)

- Base case obj: 712281.64
- Heuristic solution:
total_bus_cost 1.65362151e-02
total_load_benefit $1.25961077 \mathrm{e}+06$
total_gen_cost 5.44767392e+05
total_line_cost $0.00000000 \mathrm{e}+00$
total_xfmr_cost 0.00000000e+00
objective 714843.36
31.30 seconds 227 iterations
+6.8 seconds +27 iterations (rounding)

## Algorithm outline

1. Find good solution to base case by migrating from prior solution
2. For each contingency, migrate from the base case solution
3. Migration $=$ use the reduced dimensionality heuristic
4. Appropriately handle binary variables (more, below).
5. MPI implementation to four nodes (each node $=16$ cores)

## Binary variables

1. MINLP branch-and-bound code in Knitro was not used - problems too large in GO2.
2. Those binary variables not fixed by dimensionality reduction are addressed by progressively relaxing, rounding, and resolving.
3. Final solve with all integer variables fixed.
4. Knitro solves warm-started.
5. Occasionally this procedure fails - in that case our algorithm retreats, unfixes some of the binary variables, and re-runs Knitro.

## Basic Details

1. Implementation in Python. Why?

- Incorporate evaluation code into our code.
- We would have done it in C, but not enough time.

2. We used AMPL to interface with Knitro. Why?

- Good preprocessor.
- Efficient automatic differentiation.

The Achylles' heel of log barrier methods:
compute Hessian of constraints.
3. Not enough time to do as much as we wanted.

- Last scoring event overlapped with start of bad semester.
- I introduced a low-level bug within a one-line command.

## Datasets in Final Event: 22 networks

- Buses: 403-31,777
- Contingencies: 54-1800

## PRIZES

For Challenge 2, the ARPA-E Benchmark team is not prize eligible and does not occupy a rank during the consideration of prize awards.
